ABSTRACT

The aim of this case report is to present the life saving use of extracorporeal membrane oxygenation (ECMO) in an obstetric patient with acute cardiorespiratory collapse following massive bleeding caused by an atonic uterus post partum. A 39-year-old patient, following a spontaneous abortion at 21 weeks of pregnancy, developed uterine atony and massive bleeding and was ultimately referred to the operating room for an emergent hysterectomy. Postoperatively, she was referred to the intensive care unit (ICU) where she developed severe acute respiratory distress syndrome (ARDS) that was successfully treated by employing ECMO. Following discontinuation of ECMO, her treatment was further complicated by a manifest hemolytic transfusion reaction. Although extensive testing was done to establish the cause of this reaction, we were unable to find it. The patient responded well to treatment with erythropoietin (EPO) and corticosteroids as well as a restrictive transfusion regime. This treatment pointed to a possible immune reaction to massive transfusions of blood products. This case demonstrated the importance of early aggressive treatment using ECMO in reversal of life threatening ARDS, as well as the need for a judicious approach when transfusing blood products.

Key words: ECMO (extracorporeal membrane oxygenation), hemorrhagic diathesis, obstetric patients

INTRODUCTION

The treatment of patients with cardiorespiratory failure frequently requires the use of extracorporeal membrane oxygenation (ECMO). There have been clear demonstrations of its benefit in the general population of patients, with various indications. (1)

Successful use of ECMO immediately postpartum has been reported in several case studies in obstetric patients with various indications. (2-8)

In this report, we present a complex case of an obstetric patient with massive hemorrhage after a spontaneous abortion at 21 weeks of gestation. There was implementation of ECMO, as a life saving measure, which allowed the recovery of the patient's cardiorespiratory functions.

CASE PRESENTATION

A 39-year-old female patient, at 21 weeks of gestation of a previously uncomplicated pregnancy, was referred to the delivery room due to suspected leakage of amniotic fluid. The first ultrasound exam revealed a healthy live female fetus with biometry corresponding to 21 weeks of gestation. Contractions appeared, amniotic membranes ruptured spontaneously, and five hours later, a dead fetus weighing 480 g was miscarried. Placental and decidual tissues were removed instrumentally during short intravenous anesthesia. Massive vaginal bleeding and hemodynamic insta-

bility complicated the early postpartum period; therefore, the patient was subjected to repeated curettage to establish control of bleeding. Bleeding continued, until finally, the patient underwent emergent transabdominal hysterectomy.

Preoperatively drawn coagulation tests showed the development of severe coagulopathy (DIC). The attending anesthesiologist instituted a massive transfusion protocol. Intraoperatively, the patient received 3480 mL of packed red blood cells, 2040 mL of freshly frozen plasma (FFP), and 700 mL of packed thrombocytes using a rapid infusion system. Despite attempts at hemodynamic stabilization, which besides blood and volume replacement also included a continuous infusion of vasoactive drugs, the patient went into short cardiac arrest twice during the operation and was successfully resuscitated on both occasions. The patient also developed signs of acute respiratory distress (ARDS), manifested by extreme difficulty at maintaining mechanical ventilation and massive alveolar discharge.

She was admitted to the intensive care unit (ICU) postoperatively, where hemodynamic and respiratory instability continued. Hypoxemia developed (PaO₂/FiO₂ ratio of 67 on day two with FiO₂>80%) despite aggressive mechanical respiratory support, and therefore, ECMO (Maquet Cardiohelp; Hirlingen, Germany) was indicated. In addition, due to developing acute renal failure, continuous veno-venous hemodialysis (CVVHD) ((Gambro Lundia; Lund, Sweden) was also needed.

Throughout the early period, continuing coagulopathy and manifest bleeding further complicated treatment, because of which, massive transfusions were still needed.

During the 8 days of ECMO treatment, the patient achieved adequate respiratory parameters and the system was decannulated. ECMO clinical course is displayed in table 1. After 15 days of treatment, renal function recovered and CVVHD was discontinued.

Sedation was discontinued at day 18 and the patient slowly regained consciousness during the next few days. She fully awoke and was extubated on day 29 of treatment.

However, from day 13 of treatment, we ob-

served an increased level of hemolysis and an increase in serum bilirubin levels. This trend continued throughout the following weeks. Direct Coombs tests, performed on several occasions, confirmed the presence of agglutinated antibodies on the surface of erythrocytes. Further diagnostic tests were unable to establish the target of antibody agglutination. Tests done to establish the presence of circulating irregular antibodies were negative on multiple occasions. Following consultations with a hematologist, we attempted plasmapheresis several times. This proved unsuccessful in treating the hemolytic reaction, and on day 33, corticosteroid treatment and application of erythropoietin (EPO) commenced. We also started treatment with Folic acid and iron supplements and implemented a restrictive regimen of transfusion therapy.

Ultimately, these treatments proved successful, and on day 40, we observed a drop in the rate of hemolysis and serum bilirubin levels for the first time. During the remaining 11 days of treatment, the rate of hemolysis, hemoglobin, and hematocrit values slowly normalized.

The patient also underwent several surgical procedures during her ECMO treatment to achieve control of bleeding and evacuate hematomas. These are listed in table 2.

Finally, on day 55 of treatment, we released the patient to a medical team for air transport to her homeland.

Table 1. Clinical ECMO course.

Day of ICU treatment	Day 2	Day 3	Day 4	Day 5	Day 6	Day 7	Day 8	Day 9
Day of ECMO treatment	Day 1	Day 2	Day 3	Day 4	Day 5	Day 6	Day 7	Day 8
pH	7.17	7.47	7.45	7.39	7.55	7.50	7.50	7.47
pCO ₂ (kPa)	5.7	3.9	4.9	5.6	3.6	3.1	4.8	4.9

ACT, activated clotting time; FFP, Freshly Frozen Plasma units transfused; Hb, Hemoglobin; Htc, Hematocrit; LPM, litres per minute; RBC, Red Blood Cells units transfused; RPM, revolutions per minute; oxy, oxygenator.

Table 2. Surgical interventions.

Day of treatment	Type of intervention
Day 2	Chest drainage
Day 2	ECMO Cannulation
Day 2	Emergent decompressive laparotomy
Day 3	Relaparotomy, evacuation of intraabdominal hematoma, tamponade
Day 5	Relaparotomy, drainage and lavage, retamponade
Day 7	Evacuation of intraabdominal hematoma, retamponade
Day 8	Evacuation of intraabdominal hematoma, retamponade
Day 9	ECMO decannulation
Day 10	Peritoneal lavage and drainage
Day 12	Peritoneal lavage and drainage
Day 14	Peritoneal lavage and drainage
Day 16	Peritoneal lavage and drainage, abdominal wall reconstruction
Day 32	Cystoscopy
Day 34	Relaparotomy, drainage and lavage, evacuation of intraabdominal hematoma
Day 40	Relaparotomy, drainage and lavage, evacuation of intraabdominal hematoma

DISCUSSION

Postpartum hemorrhage is one of the leading causes of maternal mortality. According to World Health Organization (WHO) statistics, severe bleeding accounts for 27% of all deaths in the postpartum period. (9)

Use of ECMO in obstetric patients has been described before in cases such as ARDS, (2) transfusion related acute lung injury (TRALI) following transfusion, (4) amniotic fluid embolism, (3) cardiomyopathy, (5) and for management of cardiorespiratory collapse following massive bleeding. (6,7)

In this case, we reached the decision to commence treatment with ECMO very early in the course of treatment, primarily due to severe ARDS. We presumed that cardiac failure and ARDS in this case were the results of hypovolemic shock and subsequent massive volume resuscitation.

Commencing ECMO in a patient with impaired coagulation is linked with risks in worsening the hemorrhagic diathesis. However, according to Extracorporeal Life Support Organization Guidelines, only active intracranial hemorrhage is considered to be a contraindication to ECMO. (10)

Because of the patient's severe condition, and keeping in mind all potential risks in-

volved, we attempted ECMO as a life-saving measure. Lamb et al. have shown that there can be successful management of ECMO bleeding complications in patients with primary respiratory failure. (8) According to ECMO guidelines, there are no contraindications of surgical procedures during treatment; in fact, early aggressive treatment targeting potential causes of cardiorespiratory collapse are encouraged. (10)

Bleeding complications in our patient continued throughout and this resulted in continued massive transfusions during early stages of ECMO. CVVHD augmented ECMO treatment due to manifest acute renal failure.

Further treatment, following cardiorespiratory stabilization and recovery of renal function, was complicated by a hemolytic reaction. Initially, we assumed this was due to the extensive volume of extracorporeal circulation involved; however, the trend continued and in fact worsened after discontinuation of extracorporeal support. Later, we assumed this was a result of an immune reaction to large volumes of blood products transfused throughout treatment. Direct Coombs test done on day 10 of treatment seemed to confirm this, as agglutinated antibodies were found on the surface of red blood cells (RBCs). However, further immunologic testing

failed to prove the existence of circulating antibodies, i.e., we were unable to find the target of this immune reaction. This possibly explains why our attempted treatment with plasmapheresis was unsuccessful. However, despite this, the most likely explanation for the continued hemolytic reaction continued to be an immune response of our patient's body to transfused blood products.

Because of this assumed mechanism, we decided to commence treatment with EPO to stimulate erythropoiesis, together with a restrictive regime of blood transfusion, which allowed for lower levels of hemoglobin and hematocrit before transfusing RBCs. Corticosteroid therapy was also started due to this assumed immunologic mechanism. The patient responded well to these treatments and fully recovered.

CONCLUSION

Despite potential misgivings of commencing ECMO in an actively bleeding patient with impaired coagulation, our case clearly demonstrates that this method has a place in the treatment of acute cardiorespiratory failure. This case has also shown that, when indicated, surgical procedures should be done in such a patient. The treating physicians should always be watchful for possible bleeding complications, and weigh

the potential risks and benefits before commencing ECMO, as well as any other treatment.

This case also clearly shows the need for a judicious approach when transfusing blood products in such patients.

ACKNOWLEDGMENT

We would like to thank the patient and her family for kindly agreeing to have her case history shared.
